HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers. L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

A survey of techniques for predicting earthquake ground

² motions for engineering purposes

3 John Douglas & Hideo Aochi

5 Received: date / Accepted: date

Abstract Over the past four or five decades many advances have been made in earth-6 quake ground-motion prediction and a variety of procedures have been proposed. Some 7 of these procedures are based on explicit physical models of the earthquake source, 8 travel-path and recording site while others lack a strong physical basis and seek only 9 to replicate observations. In addition, there are a number of hybrid methods that seek 10 to combine benefits of different approaches. The various techniques proposed have their 11 adherents and some of them are extensively used to estimate ground motions for engi-12 neering design purposes and in seismic hazard research. These methods all have their 13 own advantages and limitations that are not often discussed by their proponents. 14

The purposes of this article are to: summarise existing methods and the most important references, provide a family tree showing the connections between different methods and, most importantly, to discuss the advantages and disadvantages of each method.

 $_{20}$ ground motion \cdot ground-motion prediction

21 1 Introduction

The accurate estimation of the characteristics of the ground shaking that occurs during 22 damaging earthquakes is vital for efficient risk mitigation in terms of land-use planning 23 and the engineering design of structures to adequately withstand these motions. This 24 article has been provoked by a vast, and rapidly growing, literature on the development 25 of various methods for ground-motion prediction. In total, this article surveys roughly 26 two dozen methods proposed in the literature. Only about half are commonly in use 27 today. Some techniques are still in development and others have never been widely 28 used due to their limitations or lack of available tools, constraints on input parameters 29 or data for their application. 30

Earthquake ground-motion estimation that transforms event parameters, e.g. mag-31 nitude and source location, to site parameters, either time-histories of ground motions 32 or strong-motion parameters (e.g. peak ground acceleration, PGA, or response spectral 33 displacement) is a vital component within seismic hazard assessment be it probabilistic 34 or deterministic (scenario-based). Ground-motion characteristics of interest depend on 35 the structure or effects being considered (e.g. McGuire 2004). At present, there are a 36 number of methods being used within research and engineering practice for ground-37 motion estimation; however, it is difficult to understand how these different procedures 38 relate to each another and to appreciate their strengths and weaknesses. Hence, the 39 choice of which technique to use for a given task is not easy to make. The purpose of 40 this article is to summarise the links between the different methods currently in use 41

today and to discuss their advantages and disadvantages. The details of the methods 42 will not be discussed here; these can be found within the articles cited. Only a brief 43 description, list of required input parameters and possible outputs are given. The au-44 dience of this article includes students and researchers in engineering seismology but 45 also seismic hazard analysts responsible for providing estimates for engineering projects 46 and earthquake engineers seeking to understand limits on the predictions provided by 47 hazard analyses. Numerous reviews of ground-motion simulation techniques have been 48 published (e.g. Aki 1982; Shinozuka 1988; Anderson 1991; Erdik and Durukal 2003) 49 but these have had different aims and scopes to this survey. 50

Only methods that can be used to estimate ground motions of engineering signifi-51 cance are examined here, i.e. those motions from earthquakes with moment magnitude 52 M_w greater than 5 at source-to-site distances less than 100 km for periods between 0 to 53 4s (but extending to permanent displacements for some special studies). In addition, 54 focus is given to the estimation of ground motions at flat rock sites since it is common 55 to separate the hazard at the bedrock from the estimation of site response (e.g. Dowrick 56 1977) and because site response modelling is, itself, a vast topic (e.g. Heuze et al 2004). 57 Laboratory models, including foam models (e.g. Archuleta and Brune 1975), are not 58 included because it is difficult to scale up to provide engineering predictions from such 59 experiments. 60

Section 2 summarises the different procedures that have been proposed within a series of one-page tables (owing to the vast literature in this domain, only brief details can be given) and through a diagram showing the links between the methods. The problem of defining an earthquake scenario is discussed in Section 3. Section 4 is concerned with the testing of methods using observations. The article concludes with a discussion of how to select the most appropriate procedure for a given task.

⁶⁷ 2 Summaries of different procedures

As described by Ólafsson et al (2001) there are basically two approaches to the con-68 struction of models for the prediction of earthquake ground motions: the mathematical 69 approach, where a model is analytically based on physical principles, and the experi-70 mental one, where a mathematical model, which is not necessarily based on physical 71 insight, is fitted to experimental data. In addition, there are hybrid approaches com-72 bining elements of both philosophies. Earthquakes are so complex that physical insight 73 alone is currently not sufficient to obtain a reasonable model. Ólafsson et al (2001) 74 term those models that only rely on measured data 'black-box' models. 75

Figure 1 summarises the links between the different methods described in Tables 1 76 to 22. Each table briefly: 1) describes the method; 2) lists the required input parameters 77 (bold for those parameters that are invariably used, italic for parameters that are 78 occasionally considered and normal font for those parameters that are often implicitly, 79 but not often explicitly, considered) and the outputs that can be reliably obtained; 3) 80 lists a maximum of a dozen key references (preference is given to: the original source 81 of the method, journal articles that significantly developed the approach and review 82 articles) including studies that test the approach against observations; 4) lists the 83 tools that are easily available to apply approach (public domain programs with good 84 documentation help encourage uptake of a method¹); 5) gives the rough level of use 85 of the technique in practice and in research; and finally 6) summarises the advantages 86 and disadvantages/limitations of the method. The following sections introduce each of 87 the four main types of methods. 88

 1 Some of the programs for ground-motion prediction availare able for download from the ORFEUS Seismological Software Library (http://www.orfeus-eu.org/Software/softwarelib.html).

Fig. 1 Summary of the approximate date when a method was developed on the x-axis, links to other approaches and the level of detail of the scenario modelled on the y-axis. Boxes indicate those methods that are often used in research and/or practice.

6

⁸⁹ 2.1 Empirical methods

The three methods described in this section are closely based on strong ground motion 90 observations. Such empirical techniques are the most straightforward way to predict 91 ground motions in future earthquakes and they are based on the assumption that 92 shaking in future earthquakes will be similar to that observed in previous events. The 93 development of these methods roughly coincided with the recording of the first strong-94 motion records in the 1930s but they continue to be improved. Empirical methods 95 remain the most popular procedure for ground-motion prediction, especially in engi-96 neering practice. Tables 1 to 3 summarise the three main types of empirical methods. 97

98	[Table 1 about here.]
99	[Table 2 about here.]
100	[Table 3 about here.]

101 2.2 Black-box methods

This section describes four methods (Tables 4 to 7) that can be classified as black-box 102 approaches because they do not seek to accurately model the underlying physics of 103 earthquake ground motion but simply to replicate certain characteristics of strong-104 motion records. They are generally characterised by simple formulations with a few 105 input parameters that modify white noise so that it more closely matches earthquake 106 shaking. These methods were generally developed in the 1960s and 1970s for engineer-107 ing purposes to fill gaps in the small observational datasets then available. With the 108 great increase in the quantity and quality of strong-motion data and the development 109 of powerful techniques for physics-based ground-motion simulation, this family of pre-110

diction techniques has become less important although some of the procedures are still
 used in engineering practice.

117 2.3 Physics-based methods

Although this class of methods was simply called the 'mathematical approach' by 118 Ólafsson et al (2001), the recent advances in the physical comprehension of the dynamic 119 phenomena of earthquakes and in the simulation technology means that we prefer the 120 name 'physics-based methods'. These techniques often consist of two stages: simulation 121 of the generation of seismic waves (through fault rupture) and simulation of wave 122 propagation. Due to this separation it is possible to couple the same source model with 123 differing wave propagation approaches or different source models with the same wave 124 propagation code (e.g. Aochi and Douglas 2006). In this survey emphasis is placed on 125 wave propagation techniques. 126

Source models that have been used extensively for ground-motion prediction include theoretical works by: Haskell (1969), Brune (1970, 1971), Papageorgiou and Aki (1983), Gusev (1983), Joyner (1984), Zeng et al (1994) and Herrero and Bernard (1994). Such insights are introduced into prescribed earthquake scenarios, called 'kinematic' source models. It is well known that the near-source ground motion is significantly affected by source parameters, such as the point of nucleation on the fault (hypocentre), rupture

velocity, slip distribution over the fault and the shape of the slip function (e.g. Miyake 133 et al 2003; Mai and Beroza 2003; Tinti et al 2005; Ruiz et al 2007). This aspect is 134 difficult to take into account in empirical methods. Recently it has become possible to 135 introduce a complex source history numerically simulated by pseudo- or fully-dynamic 136 modelling (e.g. Guatteri et al 2003, 2004; Aochi and Douglas 2006; Ripperger et al 2008) 137 into the prediction procedure. Such dynamic simulations including complex source 138 processes have been shown to successfully simulate previous large earthquakes, such as 139 the 1992 Landers event (e.g. Olsen et al 1997; Aochi and Fukuyama 2002). This is an 140 interesting and on-going research topic but we do not review them in this article. 141

All of the physics-based deterministic methods convolve the source function with 142 synthetic Green's functions (the Earth's response to a point-source double couple) to 143 produce the motion at ground surface. Erdik and Durukal (2003) provide a detailed 144 review of the physics behind ground-motion modelling and show examples of ground 145 motions simulated using different methods. Tables 8 to 18 summarise the main types 146 of physics-based procedures classified based on the method used to calculate the syn-147 thetic seismograms in the elastic medium for a given earthquake source. Most of these 148 are based on theoretical concepts introduced in the 1970s and 1980s and intensively 149 developed in the past decade when significant improvements in the understanding 150 of earthquake sources and wave propagation (helped by the recording of near-source 151 ground motions) were coupled with improvements in computer technology to develop 152 powerful computational capabilities. Some of these methods are extensively used for 153 research purposes and for engineering projects of high-importance although most of 154 them are rarely used in general engineering practice due to their cost and complexity. 155

167 2.4 Hybrid methods

To benefit from the advantages of two (or more) different approaches and to overcome 168 some of their disadvantages a number of hybrid methods have been proposed. These 169 are summarised in Tables 19 to 22. These techniques were developed later than the 170 other three families of procedures, which are the bases of these methods. Since their de-171 velopment, mainly in the 1980s and 1990s, they have been increasingly used, especially 172 for research purposes. Their uptake in engineering practice has been limited until now, 173 although they seem to be gaining in popularity due to the engineering requirement for 174 broadband time-histories, e.g. for soil-structure interaction analyses. 175

176

[Table 19 about here.]

180 3 Earthquake scenario

Before predicting the earthquake ground motions that could occur at a site it is nec-181 essary to define an earthquake scenario or scenarios, i.e. earthquake(s) that need(s) 182 to be considered in the design (or risk assessment) process for the site. The methods 183 proposed in the literature to define these scenarios (e.g. Dowrick 1977; Hays 1980; Re-184 iter 1990; Anderson 1997a; Bazzurro and Cornell 1999; Bommer et al 2000) are not 185 discussed here. In this section the focus is on the level of detail required to define a 186 scenario for different ground-motion prediction techniques, which have varying degrees 187 of freedom. In general, physics-based (generally complex) methods require more pa-188 rameters to be defined than empirical (generally simple) techniques. As the number 189 of degrees of freedom increases sophisticated prediction techniques can model more 190 specific earthquake scenarios, but it becomes difficult to constrain the input parame-191 ters. The various methods consider different aspects of the ground-motion generation 192 process to be important and set (either explicitly or implicitly) different parameters 193 to default values. However, even for methods where a characteristic can be varied it is 194 often set to a standard value due to a lack of knowledge. In fact, when there is a lack 195 of knowledge (epistemic uncertainty) the input parameters should be varied within a 196 physically-realistic range rather than fixed to default values. Care must be taken to 197 make sure that parameters defining a scenario are internally consistent. For example, 198

asperity size and asperity slip contrast of earthquake ruptures are generally inversely
 correlated (e.g. Bommer et al 2004).

The basic parameters required to define a scenario for almost all methods are mag-201 nitude and source-to-site distance (note that, as stated in Section 1, hazard is generally 202 initially computed for a rock site and hence site effects are not considered here). In 203 addition, other gross source characteristics, such as the style-of-faulting mechanism, 204 are increasingly being considered. An often implicit general input variable for simple 205 techniques is 'seismotectonic regime', which is explicitly accounted for in more com-206 plex approaches through source and path modelling. In this article, we assume that 207 kinematic source models (where the rupture process is a fixed input) are used for 208 ground-motion simulations. Dynamic source modelling (where the rupture process is 200 simulated by considering stress conditions) is a step up in complexity from kinematic 210 models and it remains mainly a research topic that is very rarely used for generating 211 time-histories for engineering design purposes. Dynamic rupture simulations have the 212 advantage over kinematic source models in proposing various possible rupture scenar-213 ios of different magnitudes for a given seismotectonic situation (e.g. Anderson et al 214 2003; Aochi et al 2006). However, it is still difficult to tune the model parameters for 215 practical engineering purposes (e.g. Aochi and Douglas 2006) (see Section 2.3 for a 216 discussion of dynamic source models). 217

Many factors (often divided into source, path and site effects) have been observed to influence earthquake ground motions, e.g.: earthquake magnitude (or in some approaches epicentral macroseismic intensity), faulting mechanism, source depth, fault geometry, stress drop and direction of rupture (directivity); source-to-site distance, crustal structure, geology along wave paths, radiation pattern and directionality; and site geology, topography, soil-structure interaction and nonlinear soil behaviour. The

combination of these different, often inter-related, effects leads to dispersion in ground 224 motions. The varying detail of the scenarios (i.e. not accounting for some factors while 225 modelling others) used for the different techniques consequently leads to dispersion 226 in the predictions. The unmodelled effects, which can be important, are ignored and 227 consequently predictions from some simple techniques (e.g. empirical ground-motion 228 models) contain a bias due to the (unknown) distribution of records used to construct 229 the model with respect to these variables (e.g. Douglas 2007). There is more explicit 230 control in simulation-based procedures. Concerning empirical ground-motion models 231 McGuire (2004) says that 'only variables that are known and can be specified before 232 an earthquake should be included in the predictive equation. Using what are actually 233 random properties of an earthquake source (properties that might be known after an 234 earthquake) in the ground motion estimation artificially reduces the apparent scat-235 ter, requires more complex analysis, and may introduce errors because of the added 236 complexity.' 237

In empirical methods the associated parameters that cannot yet be estimated be-238 fore the earthquake, e.g. stress drop and details of the fault rupture, are, since observed 239 ground motions are used, by definition, within the range of possibilities. Varying num-240 bers of these parameters need to be chosen when using simulation techniques, which 241 can be difficult. On the other hand, only a limited and unknown subset of these param-242 eters are sampled by empirical methods since not all possible earthquakes have been 243 recorded. In addition, due to the limited number of strong-motion records from a given 244 region possible regional dependence of these parameters cannot usually be accounted 245 for by empirical procedures since records from a variety of areas are combined in order 246 to obtain a sufficiently large dataset. 247

Various prediction methods account for possible regional dependence (e.g. Douglas 248 2007) in different ways. Methods based on observed ground motions implicitly hope 249 that the strong-motion records capture the complete regional dependence and that the 250 range of possible motions is not underestimated. However, due to limited databanks 251 it is not often possible to only use records from small regions of interest; data from 252 other areas usually need to be imported. Physics-based methods explicitly model re-253 gional dependence through the choice of input parameters, some of which, e.g. crustal 254 structure, can be estimated from geological information or velocimetric (weak-motion) 255 data, while others, e.g. stress parameters, can only be confidently estimated based 256 on observed strong-motion data from the region. If not available for a specific region 257 parameters must be imported from other regions or a range of possible values assumed. 258 Although this article does not discuss site effects nor their modelling, it is important 259 that the choice of which technique to use for a task is made considering the potential 260 use of the ground-motion predictions on rock for input to a site response analysis. For 261 example, predictions from empirical methods are for rock sites whose characteristics 262 (e.g. velocity and density profiles and near-surface attenuation) are limited by the ob-263 servational database available and therefore the definition of rock cannot, usually, be 264 explicitly defined by the user; however, approximate adjustments to unify predictions 265 at different rock sites can be made (e.g. Cotton et al 2006). In addition, the character-266 istics of the rock sites within observational databases are generally poorly known (e.g. 267 Cotton et al 2006) and therefore the rock associated with the prediction is ill-defined. 268 In contrast, physics-based techniques generally allow the user to explicitly define the 260 characteristics of the rock site and therefore more control is available. The numerical 270 resolution of each method puts limits on the velocities and thicknesses of the suffi-271 ciently layers that can be treated. Black-box approaches generally neglect site effects 272

and, when they do, the parameters for controlling the type of site to use are, as in empirical techniques, constrained based on (limited) observational databases.

275 4 Testing of methods

Predicted ground motions should be compared to observations for the considered site, 276 in terms of amplitude, frequency content, duration, energy content and more difficult 277 to characterise aspects, such as the 'look' of the time-histories. This verification of the 278 predictions is required so that the ground-motion estimates can be used with confi-279 dence in engineering and risk analyses. Such comparisons take the form of either point 280 comparisons for past earthquakes (e.g. Aochi and Madariaga 2003), visually checking 281 a handful of predictions and observations in a non-systematic way, or more general 282 routine validation exercises, where hundreds of predictions and observations are statis-283 tically compared to confirm that the predictions are not significantly biased and do not 284 display too great a scatter (a perfect fit between predictions and observations is not 285 expected, or generally possible, when making such general comparisons) (e.g. Atkinson 286 and Somerville 1994; Silva et al 1999; Douglas et al 2004). In a general comparison it 287 is also useful to check the correlation coefficients between various strong-motion pa-288 rameters (e.g. PGA and relative significant duration, RSD) to verify that they match 289 the correlations commonly observed (Aochi and Douglas 2006). 290

For those techniques that are based on matching a set of strong-motion intensity parameters, such as the elastic response spectral ordinates, it is important that the fit to non-matched parameters is used to verify that they are physically realistic, i.e. to check the internal consistency of the approach. For example, black-box techniques that generate time-histories to match a target elastic response spectrum can lead to time-histories with unrealistic displacement demand and energy content (Naeim andLew 1995).

A potentially useful approach, although one that is rarely employed, is to use a construction set of data to calibrate a method and then an independent validation set of data to test the predictions. Using such a two-stage procedure will demonstrate that any free parameters tuned during the first step do not need further modifications for other situations. Such a demonstration is important when there is a trade-off between parameters whereby various choices can lead to similar predicted ground motions for a given scenario.

One problem faced by all validation analysis is access to all the required independent 305 parameters, such as local site conditions, in order that the comparisons are fair. If a 306 full set of independent variables is not available then assumptions need to be made, 307 which can lead to uncertainty in the comparisons. For example, Boore (2001), when 308 comparing observations from the Chi-Chi earthquake to shaking predicted by various 309 empirical ground-motion models, had to make assumptions on site classes due to poor 310 site information for Taiwanese stations. These assumptions led to a lack of precision 311 in the level of over-prediction of the ground motions. 312

Until recently most comparisons between observations and predictions were visual 313 or based on simple measures of goodness-of-fit, such as: the mean bias and the overall 314 standard deviation sometimes computed using a maximum-likelihood approach (Spu-315 dich et al 1999). Scherbaum et al (2004) develop a statistical technique for ranking 316 various empirical ground-motion models by their ability to predict a set of observed 317 ground motions. Such a method could be modified for use with other types of pre-318 dictions. However, the technique of Scherbaum et al (2004) relies on estimates of the 319 scatter in observed motions, which are difficult to assess for techniques based on ground-320

motion simulation, and the criteria used to rank the models would probably require 321 modification if applied to other prediction techniques. Assessment of the uncertainty 322 in simulations requires considering all sources of dispersion: modelling (differences be-323 tween the actual physical process and the simulation), random (detailed aspects of the 324 source and wave propagation that cannot be modelled deterministically at present) 325 and parametric (uncertainty in source parameters for future earthquakes) (Abraham-326 son et al 1990). The approach developed by Abrahamson et al (1990) to split total 327 uncertainty into these different components means that the relative importance of dif-328 ferent source parameters can be assessed and hence aids in the physical interpretation 329 of ground-motion uncertainty. 330

In addition to this consideration of different types of uncertainty, work has been 331 undertaken to consider the ability of a simulation technique to provide adequate pre-332 dictions not just for a single strong-motion intensity parameter but many. Anderson 333 (2004) proposes a quantitative measure of the goodness-of-fit between synthetic and 334 observed accelerograms using ten different criteria that measure various aspects of the 335 motions, for numerous frequency bands. This approach could be optimized to require 336 less computation by adopting a series of strong-motion parameters that are poorly 337 correlated (orthogonal), and hence measure different aspects of ground motions, e.g. 338 amplitude characterised by PGA and duration characterised by RSD. A goodness-of-fit 339 approach based on the time-frequency representation of seismograms, as opposed to 340 strong-motion intensity parameters as in the method of Anderson (2004), is proposed 341 by Kristeková et al (2006) to compare ground motions simulated using different com-342 puter codes and techniques. Since it has only recently been introduced this procedure 343 has yet to become common but it has the promise to be a useful objective strategy for 344 the validation of simulation techniques by comparing predicted and observed motions 345

16

and also by internal comparisons between methods. Some comprehensive comparisons
of the results from numerical simulations have been made in the framework of recent
research projects and workshops (e.g. Day et al 2005; Chaljub et al 2007b)

If what is required from a method is a set of ground motions that include the 349 possible variability in shaking at a site from a given event then it is important to 350 use a method that introduces some randomness into the process (e.g. Pousse et al 351 2006) to account for random and parametric uncertainties. For example, results from 352 physically-based simulation techniques will not reproduce the full range of possible 353 motions unless a stochastic element is introduced into the prediction, through the 354 source or path. However, if what is required from a technique is the ability to give 355 the closest prediction to an observation then this stochastic element is not necessarily 356 required. 357

358 5 Synthesis and conclusions

359 Dowrick (1977) notes that '[a]s with other aspects of design the degree of detail entered into selecting dynamic input [i.e. ground-motion estimates] will depend on the size 360 and vulnerability of the project'. This is commonly applied in practice where simple 361 methods (GMPEs, representative accelerograms or black-box methods) are applied for 362 lower importance and less complex projects whereas physics-based techniques are used 363 for high importance and complex situations (although invariably in combination with 364 simpler methods). Methods providing time-histories are necessary for studies requiring 365 non-linear engineering analyses, which are becoming increasingly common. Dowrick 366 (1977) believes that 'because there are still so many imponderables in this topic only 367 the simpler methods will be warranted in most cases'. However, due to the significant 368

improvements in techniques, knowledge, experience and computing power this view 369 from the 1970s is now less valid. Simple empirical ground-motion estimates have the 370 advantage of being more defensible and are more easily accepted by decision makers 371 due to their close connection to observations. Simulations are particularly important in 372 regions with limited (or non-existent) observational databanks and also for site-specific 373 studies, where the importance of different assumptions on the input parameters can 374 be studied. However, reliable simulations require good knowledge of the propagation 375 media and they are often computationally expensive. 376

One area where physics-based forward modelling breaks down is in the simulation 377 of high-frequency ground motions where the lack of detail in source (e.g. heterogeneities 378 of the rupture process) and path (e.g. scattering) models means high frequencies are 379 poorly predicted. Hanks and McGuire (1981) state that '[e]vidently, a realistic charac-380 terization of high-frequency strong ground motion will require one or more stochastic 381 parameters that can account for phase incoherence.' In contrast, Aki (2003) believes 382 that '[a]ll these new results suggest that we may not need to consider frequencies higher 383 than about 10 Hz in Strong Motion Seismology. Thus, it may be a viable goal for strong 384 motion seismologists to use entirely deterministic modeling, at least for path and site 385 effects, before the end of the 21st century.' 386

The associated uncertainties within ground-motion prediction remain high despite many decades of research and increasingly sophisticated techniques. The unchanging level of aleatory uncertainties within empirical ground-motion estimation equations over the past thirty years are an obvious example of this (e.g. Douglas 2003). However, estimates from simulation methods are similarly affected by large (and often unknown) uncertainties. These large uncertainties oblige earthquake engineers to design structures with large factors of safety that may not be required. The selection of the optimum method for ground-motion estimation depends on what data is available for assessing the earthquake scenario, resources available and experience of the group. Currently the choice of method used for a particular study is generally controlled by the experience and preferences of the worker and the tools and software available to them rather than it being necessarily selected based on what is most appropriate for the project.

There are still a number of questions concerning ground-motion prediction that 400 need to be answered. These include the following: possible regional dependence of 401 ground motions (e.g. Douglas 2007), the effect of rupture complexity on near-source 402 ground motion (e.g. Aochi and Madariaga 2003), the spatial variability of shaking (e.g. 403 Goda and Hong 2008) and the determination of upper bounds on ground motions (e.g. 404 Strasser et al 2008). All these questions are difficult to answer at present due to the 405 lack of near-source strong-motion data from large earthquakes in many regions (little 406 near-source data exists outside the western USA, Japan and Taiwan). Therefore, there 407 is a requirement to install, keep operational and improve, e.g. in terms of spatial density 408 (Trifunac 2007), strong-motion networks in various parts of the world. In addition, the 409 co-location of accelerometers and high-sample-rate instruments using global navigation 410 satellite systems (e.g. the Global Positioning System, GPS) could help improve the 411 prediction of long-period ground motions (e.g. Wang et al 2007). 412

In addition to the general questions mentioned above, more specific questions related to ground-motion prediction can be posed, such as: what is the most appropriate method to use for varying quality and quantity of input data and for different seismotectonic environments? how can the best use be made of the available data? how can the uncertainties associated with a given method be properly accounted for? how can the duration of shaking be correctly modelled? These types of questions are rarely explicitly investigated in articles addressing ground-motion prediction. In addition, more
detailed quantitative comparisons of simulations from different methods for the same
scenario should be conducted through benchmarks.

Over time the preferred techniques will tend to move to the top of Figure 1 (more 422 physically based approaches requiring greater numbers of input parameters) (e.g. Field 423 et al 2003) since knowledge of faults, travel paths and sites will become sufficient to 424 constrain input parameters. Such predictions will be site-specific as opposed to the 425 generic estimations commonly used at present. Due to the relatively high cost and 426 difficulty of ground investigations, detailed knowledge of the ground subsurface are 427 likely to continue to be insufficient for fully numerical simulations for high-frequency 428 ground motions, which require data on 3D velocity variations at a scale of tens of 429 metres. In the distant future when vast observational strong-motion databanks exist 430 including records from many well-studied sites and earthquakes, more sophisticated 431 versions of the simplest empirical technique, that of representative accelerograms, could 432 be used where selections are made not just using a handful of scenario parameters but 433 many, in order to select ground motions from scenarios close to that expected for a 434 study area. 435

Acknowledgements The design of the diagram in this article has benefited from advice contained in the book by Tufte (2006). Some of the work presented in this article was funded by the ANR project 'Quantitative Seismic Hazard Assessment' (QSHA). The rest was funded by internal BRGM research projects. We thank the rest of the BRGM Seismic Risks unit for numerous discussions on the topics discussed in this article. Finally, we thank two anonymous reviewers for their careful and detailed reviews, which led to significant improvements to this article.

Table 1 Method of representative accelerograms

Description of method

Records are chosen from databanks containing accelerograms that are appropriate for the considered site. Selection is often made considering the magnitude and distance (and occasionally other characteristics such as style-of-faulting) of the scenario event. Records with elastic response spectra that match a design spectrum are often preferred. After selection scaling of the amplitude (and occasionally the time scale) is often performed to corrected for differences to the design ground-motion parameters (e.g. PGA). A modern variant of this technique that is increasing in popularity is the minor adjustment of time-histories so that their response spectra better match the design spectrum. Input parameters Outputs Key references Guzman and Jennings (1976), Dowrick Magnitude, Scaled (modified) (1977), Campbell (1986), Joyner and distance, denatural accelerogram reliable up Boore (1988), Shome et al (1998), Bommer sign response spectrum. to 1-4s for anaet al (2000), Bommer and Ruggeri (2002), seis-Bommer and Acevedo (2004), Baker motectonic regime. logue or 10s for source depth, digital (Akkar and and Cornell (2006), Watson-Lamprey and style-of-faulting Bommer 2006) Abrahamson (2006), Beyer and Bommer (2007), Hancock et al (2008) Available tools Used in research Used in practice Various websites (e.g. Ambraseys et al Often Very often al 2004b) and CD ROMs (e.g. Ambraseys though they are et al 2004a) providing accelerograms; RSPrarely called MATCH2005 (Hancock et al 2006); RAS-'representative CAL (Silva and Lee 1987); WAVGEN accelerograms'. (Mukherjee and Gupta 2002) Disadvantages/limitations Advantages Rapid: straightforward: many available Still lack of near-source records from large

records from Internet sites and CD ROM collections; can account for effects (e.g. near-field pulses) that are not well modelled by other methods; well established; since the ground motions have occurred in the past, they are physically possible; more easily understood and accepted by decision makers since based on observations; only requires standard scenario characteristics; includes ground-motion variability; can provide triaxial time-histories consistent with observed correlations between components. Disadvantages/limitations Still lack of near-source records from large events (hence difficult to know if observations are well representative of the true range of possible motions or sampling artifact); difficult to find records to match scenario characteristics in addition to magnitude and distance; small databanks for most regions (outside California and Japan); often implicit assumption is that host and target regions have similar characteristics (or that strong motions are not dependent on region); difficult to ascertain whether certain records are applicable elsewhere due to particular site or source effects; scaling can have significant impact on results of dynamic analyses.

Description of method		
A databank of accelerograms and metadata from a region are collated and processed.		
Strong-motion intensity parameters (e.g. PGA) are computed for these accelerograms.		
Regression analysis is performed using a handful of source, path and site independent		
variables and the intensity parameter as the dependent variable. Less popular variants		
consist of the development of tables, graphs or neural nets for prediction purposes. The de-		
veloped models are evaluated for a given sce	nario and the results are commonly weighted.

Table 3 Methods based on macroseismic intensity-ground-motion correlations

Description of method

A databank of accelerograms and their associated macroseismic intensity (and possibly other metadata) from a region are collated and processed. Strong-motion intensity parameters (e.g. PGA) are computed for these accelerograms. Regression analysis is performed with macroseismic intensity (and possibly other parameters) as the independent variable(s) and the strong-motion parameter as the dependent variable. Assessed macroseismic site intensity is converted to a strong-motion intensity parameter using the previously derived correlation.

Available tools		Used in research Used in practice
None known		Rarely Occasionally
Advantages		Disadvantages/limitations

Rapid; straightforward; more easily understood and accepted by decision makers since based on observations; only requires standard scenario characteristics; includes ground-motion variability; historical earthquake catalogues often defined only in terms of macroseismic intensities hence less conversions required than other techniques; does not require strong-motion data if adopt data/model from another region; easier to apply ground-motion estimates for risk evaluation if vulnerability functions defined in terms of macroseismic intensity.

Output is strong-motion parameter rather than time-history; strong-motion parameter not always useful for sophisticated engineering analyses; often implicit assumption is that host and target regions have similar characteristics (or that strong motions are not dependent on region); weak statistical dependence (lack of clear physical relationship) between ground-motion parameters and intensity; intensities in catalogues are subjective and can be associated with large inaccuracies; few reliable usable correlations between intensity and different strong-motion parameters because there are many intensity scales, intensity assessment can be country-dependent and lack of intensity data from close to accelerograph stations: many intensity relationships derived using isoseismal contours, which leads to positive bias in estimated motions; applies to a generic (mainly unknown) situation so cannot account for site-specific conditions; never sure of having the correct functional form; observed data smoothed due to large scatter in observations; requires lots of records to derive correlations; at edges of dataspace predictions poorly constrained; physically basis of coefficients not always clear; ground motions from small and large events scale differently with magnitude and distance hence difficult to use weak records to predict strong motions; debate over preference for global, regional or local models; large epistemic uncertainty, mainly due to limited data.

 ${\bf Table \ 4} \ {\rm Methods \ based \ on \ stationary \ black-box \ simulations}$

Description of method		
This type of method was developed to fill in gaps in early observational databanks,		
particularly, for large earthquakes. White noise (sum of cosines with random time delays)		
is modified by filtering in the frequency domain to obtain acceleration time-histories that		
conform to the observed main characteristic	cs of earthquake ground motions.

Available tools	Used in research Used in practice
SIMQKE (Vanmarcke and Gasparini 1976), various updates and numerous similar codes	Occasionally Often
Advantages	Disadvantages/limitations
Rapid; straightforward; provides time- histories whose elastic response spectra exactly match design spectrum; only re- quires an elastic response spectrum as in- put; commonly used in past so well estab- lished; do not require knowledge of source, path and site; easy-to-use software freely available.	Do not generally involve rigorous consid- erations of the physics of the earthquakes; true ground-motion variability can be un- derestimated; too many cycles in ground motions; energy content of motions not realistic; velocity and displacement time- histories not realistic.

 ${\bf Table \ 8} \ {\rm Methods \ based \ on \ physics-based \ stochastic \ models}$

Description of method

A Fourier spectrum of ground motion is estimated using a stochastic model of the source spectrum that is transferred to the site by considering geometric decay and anelastic attenuation. The parameters that define the source spectrum and the geometric and anelastic attenuation are based on simple physical models of the earthquake process and wave propagation. These parameters are estimated by analysing many seismograms. After the Fourier spectrum at a site is estimated time-histories can be computed by adjusting and enveloping Gaussian white noise to give the desired spectrum and duration of shaking. Some authors develop equations like those developed from observational data (Table 2) based on thousands of simulations for various magnitudes and distances.

 ${\bf Table \ 9} \ {\rm Methods \ based \ on \ physics-based \ extended \ stochastic \ models}$

Description of method

The fault rupture plane is modelled as an array of subfaults. Rupture initiates at the hypocentre and spreads along the fault plane. The radiation from each subfault is modelled as in the physics-based stochastic method (Table 8). Simulations from each subfault are summed at each considered observation point (after accounting for correct time delays at observation point). The size of the subfaults controls the overall spectral shape at medium frequencies. Some authors develop equations like those developed from observational data (Table 2) based on thousands of simulations for various magnitudes and distances.

 ${\bf Table \ 10} \ {\rm Method \ based \ on \ group-velocity \ dispersion \ curves}$

Description of method

The dispersive properties of earthquake waves propagating through low-velocity layers of the crust are used to model the phase characteristics of the simulated ground motion. Higher order modes of Love and Rayleigh-wave group velocity dispersion curves are used. This technique models time variations in frequency content as well as in amplitude due to surface wave dispersion. The stochastic nature of motion is captured by random phasing. The smooth Fourier amplitude spectrum and duration used to scale the ground motions are defined based on empirical ground-motion models or correlations with macroseismic intensity (Table 2 & Table 3).

Table 12 Finite difference methods (FDM)

Description of method

Directly solve the differential equation of elastic or (viscoelastic) wave propagation in a medium. The volume is discretized, usually by equally-spaced grids, but some intelligent ways of using unstructured grids have also been proposed. Finite fault sources are usually (except when dynamically modelling the rupture process along the fault plane) treated as a series of point sources in the form of double couple forces or stress gluts corresponding to a seismic moment. As for other pure numerical methods, anelastic attenuation can be approximated as a damping factor in the elastic methods, anelastic attenuation can set the visco-elastic equations. To simulate an unbounded medium, such as the Earth, some absorbing boundary conditions should be introduced at the edges of the model space so as to avoid artificial wave reflections. Both these aspects are still research topics.

 ${\bf Table \ 19} \ {\rm Methods \ based \ on \ empirical \ Green's \ functions \ (EGF) \ (classic)}$

Description of method

Observed ground motion(s) recorded at a site (e.g. from aftershock(s) of a mainshock that is to be modelled) are collected and are used as EGF(s). EGF(s) should have same focal mechanism(s) as modelled earthquake. The modelled fault is divided into subfaults whose sizes equal the rupture area of the event(s) contributing the EGF(s). Fault rupture is simulated and the EGFs are used as the ground motion from each subfault. Therefore the simulated ground motion at a site is the weighted (moment scaling of small events and correction for radiation pattern) time-delayed (to model rupture propagation) sum of the EGFs.

Description of method			
As in the classic EG	F method (Table 19) o	bserved ground motion(s) recorded at a site	
(e.g. from aftershock	(s) of a mainshock that	is to be modelled) are collected and are used	
as $EGF(s)$. These are	as EGF(s). These are stochastically summed (using a probability density of time delays)		
so that the simulate	d ground motions are,	on average, in exact agreement with current	
knowledge on earthq	uake scaling relations.

${\bf Table \ 21} \ {\rm Hybrid \ stochastic-empirical \ method}$

Description of method

A stochastic model (Table 8) is constructed for a target region (e.g. from existing lit-			
erature). Stochastic models	erature). Stochastic models are estimated for existing empirical ground-motion models		
(for different host regions) for response spectra by finding models that lead to the min-			
imum misfit between predie	cted response spe	ectra from empirical and stochastic models.	
Response spectra are predic	cted for various m	agnitudes and distances (and other indepen-	
dent variables) by the emp	irical ground-mo	tion models and then are multiplied by the	
ratio between the response	spectrum predic	ted by the stochastic models for the target	
and host regions. These resp	ponse spectral or	dinates are then regressed to develop hybrid	
stochastic-empirical ground	l-motion models f	for the target region.

Table 22 Hybrid numerical methods

Description of method

High frequencies from one method and low frequencies from another method to get hybrid synthetic ground motions (after used matched filters to combine the two approaches) that are then used to simulate motions from large earthquakes. This approach is taken since smaller scale heterogeneity in the Earth (source, propagation path and site) is difficult to deterministically identify and our knowledge in each method is limited. Those who propose EGF or stochastic methods (e.g. Tables 8, 9, 19 and 20) to generate high frequencies assume relatively simple earthquake source description, whereas those who use semi-analytical or numerical methods (see Tables 11, 12 and 13) up to high frequencies adopt complex descriptions of the earthquake source, which have been greatly developed in the past decade. There are numerous combinations proposed in the literature.
