Abstract Modeling studies addressing daily to interannual coastal evolution typically relate shoreline change with waves, currents and sediment transport through complex processes and feedbacks. For wave-dominated environments, the main driver (waves) is controlled by the regional atmospheric circulation. Here a simple weather regime-driven shoreline model is developed for a 15-year shoreline dataset (2000–2014) collected at Truc Vert beach, Bay of Biscay, SW France. In all, 16 weather regimes (four per season) are considered. The centroids and occurrences are computed using the ERA-40 and ERA-Interim reanalyses, applying *k*-means and EOF methods to the anomalies of the 500-hPa geopotential height over the North Atlantic Basin. The weather regime-driven shoreline model explains 70% of the observed interannual shoreline variability. The application of a proven wave-driven equilibrium shoreline model to the same period shows that both models have similar skills at the interannual scale. Relation between the weather regimes and the wave climate in the Bay of Biscay is investigated and the primary weather regimes impacting shoreline change are identified. For instance, the winter zonal regime characterized by a strengthening of the pressure gradient between the Iceland low and the Azores high is associated with high-energy wave conditions

and is found to drive an increase in the shoreline erosion rate. The study demonstrates the predictability of interannual shoreline change from a limited number of weather regimes, which opens new perspectives for shoreline change modeling and encourages long-term shoreline monitoring programs.

Introduction

Sandy coasts are complex environments that are under increasing threat posed by anthropogenic pressures and climate change. Shoreline change is governed by myriad nonlinear physical processes interacting through complex feedbacks covering a wide range of spatial and temporal scales (Stive et al. 2002), challenging model developments. Although several complex process-based morphodynamic models have been developed in recent decades, simulations at large temporal scales, i.e., years, are still hardly reliable. Shoreline evolution on timescales from hours (cf. storms) to years has recently been simulated with fair skill using wave-driven empirical equilibrium-based models (e.g., Davidson and Turner 2009; Yates et al. 2009; Davidson et al. 2013; Castelle et al. 2014; Splinter et al. 2014a). These models can also reproduce the interannual shoreline variability that sometimes exceeds the seasonal variability (e.g., Castelle et al. 2014). However, model skills strongly depend on the availability and quality of wave data. The characteristics of waves reaching the coast depend strongly on remote surface atmospheric circulation (e.g., Bacon and Carter 1993; Young 1999; Woolf et al. 2002; Le Cozannet et al. 2011; Charles et al. 2012a; Martínez-Asensio et al. 2016). Because waves are the primary driver of shoreline change along most coastlines, interannual shoreline variability is expected to be related to interannual large-scale atmospheric dynamics. Therefore, directly using atmospheric conditions as inputs in shoreline models appears

as an appealing approach. This reduced-complexity strategy may also implicitly account for other drivers such as mean water level fluctuations (Ruggiero et al. 2001; Serafin and Ruggiero 2014).

Using a simple approach, Kuriyama et al. (2012) revealed that about 45% of the interannual shoreline variability measured at a NW Pacific Ocean beach can be attributed to large-scale climate fluctuations described through a combination of teleconnection pattern indices. Barnard et al. (2015) recently gave new evidence that large-scale atmospheric circulation patterns control unusual, local storm-driven shoreline change around the Pacific Basin, with enhanced erosion along the NW American coast and the SE Australian coast caused by extreme El Niño and La Niña, respectively. Studies focusing on NE Atlantic sandy coasts and climate variability have already highlighted the existence of a relationship between the North Atlantic Oscillation teleconnection (NAO) and the beach sand bar states (e.g., Masselink et al. 2014) or along-shore sediment transport (e.g., Silva et al. 2012; Idier et al. 2013). However, none of these studies addresses the potential link between the large-scale atmospheric circulation and shoreline variability. In addition, these studies used teleconnection pattern indices to characterize the large-scale atmospheric circulation, as they are freely available online and easy to use. However, it is also possible to describe large-scale atmospheric circulation and its variability by so-called weather regimes.

Weather regimes are recurrent and persistent atmospheric circulation patterns. They are usually identified by cluster analysis (Michelangeli et al. 1995) applied to daily fields of mean sea-level pressure or geopotential height (at a given pressure level) taken over an area of interest. Using this approach, the North Atlantic synoptic circulation can be accurately characterized, as atmospheric data located over the oceanic basin only are used for the weather regime computation (Cassou et al. 2004; Barrier et al. 2013, 2014).

In this paper, a simple weather regime-driven shoreline model is implemented to investigate shoreline interannual variability at Truc Vert beach, Bay of Biscay, SW France. A set of 16 seasonal weather regimes (four per season) is computed for the North Atlantic Basin and the shoreline model is tested against a shoreline dataset covering a 15-year period from 2000 to 2014. The relation between weather regimes, waves and shoreline evolution, as well as the model skills are discussed.

Physical setting

Truc Vert is a meso-macrotidal double-barred open beach backed by high and wide coastal dunes (Fig. 1a, b). The sediment consists of fine to medium sand with a mean grain size of about 0.35–0.40 mm. Truc Vert is exposed to high-energy,

seasonally modulated waves generated over the North Atlantic Ocean with a mean significant wave height H_s of 1.7 m, a mean peak wave period of 10.3 s and a dominant WNW direction (Castelle et al. 2015). Summer is characterized by the dominance of NW short waves whereas longer and larger waves coming from the WNW prevail in winter. H_s can episodically exceed 8 m during severe winter storms with a peak wave period often larger than 15 s (Castelle et al. 2015). This is illustrated in Fig. 2e based on a time series of 3-hourly H_s offshore of Truc Vert beach with the superimposed 90-day moving average over the period 2000–2014 using the wave data described in Castelle et al. (2014).

The North Atlantic atmospheric circulation is characterized by westward-tracking extra-tropical low-pressure systems over the North Atlantic Ocean, which is regularly interrupted by broadening of high-pressure systems. In winter, the North Atlantic atmospheric variability is found to be accurately characterized on a daily basis through the so-called weather regime paradigm (see, for example, Barrier et al. 2014). Four well-defined circulation patterns inherent to the atmospheric dynamics over the North Atlantic Ocean are usually identified (Vautard 1990; Cassou et al. 2004). The zonal regime (ZO) is characterized by a strengthening of the pressure gradient between the Iceland low and the Azores high. The Greenland anticyclone (GA) exhibits an opposite structure with a gradient lowering. ZO and GA correspond to the positive and negative phase of the North Atlantic Oscillation (NAO+ and NAO–), respectively (Cassou et al. 2011). The blocking regime (BL) refers to a situation in which a persistent anticyclone is located over northern Europe and Scandinavia. The Atlantic ridge (AR) is associated with a broadening of the Azores high, and is very close to the negative phase of the East Atlantic pattern (EA; Barnston and Livezey 1987; Cassou et al. 2011). Intensification of the latitudinal pressure gradient over the North Atlantic Ocean typically results in stronger westerly winds promoting energetic waves that propagate toward Truc Vert, whereas persistence of anticyclonic conditions over the North Atlantic Basin results in smaller waves. However, the overall relations between these basin-scale weather regimes and the local wave and shoreline dynamics at Truc Vert have not yet been investigated. This is addressed in this study.

Materials and methods

Shoreline data

Two topographic datasets were gathered to produce a shoreline dataset that covers a 15-year study period from 2000 to 2014. From March 2000 to March 2005, single beach profiles were collected through various means (e.g., theodolite, DGPS). From April 2005 to December 2014, with a 1-year

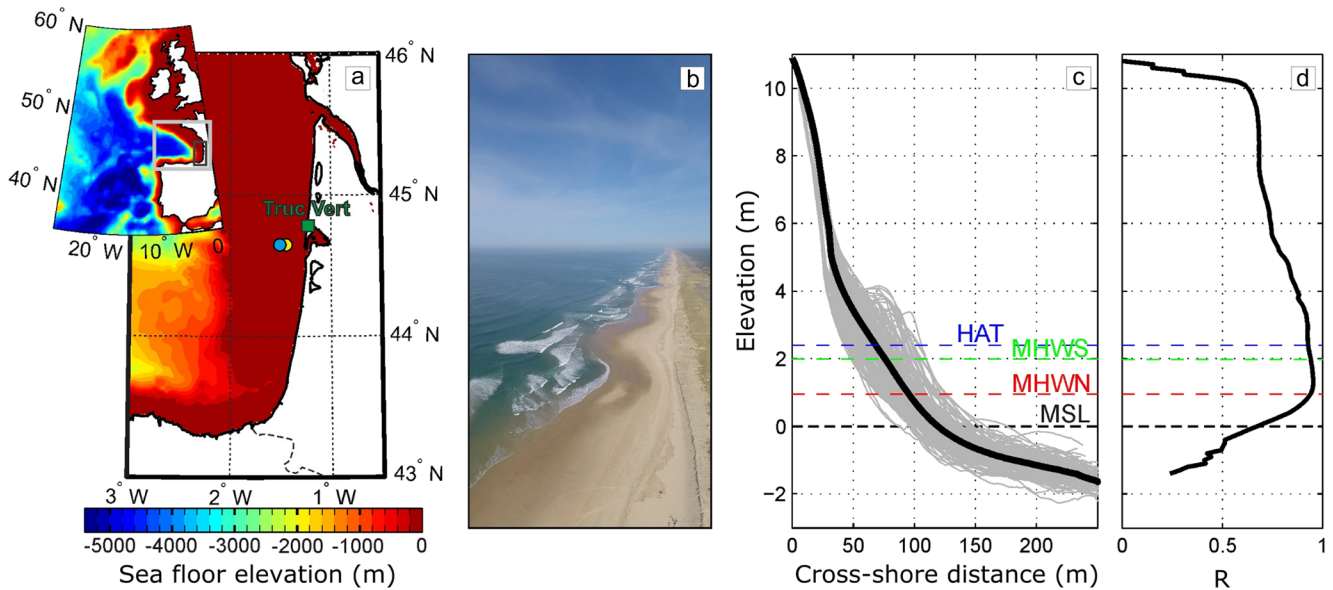

Fig. 1 **a** Truc Vert beach location (green square) in the Bay of Biscay (gray box), and buoy and wave model grid point used to produce the wave hindcast (blue and yellow dots, respectively). **b** Aerial view of Truc Vert beach. **c** Alongshore-averaged beach profiles surveyed at Truc Vert beach from April 2005 to April 2013 (gray curves) and time-

averaged mean profile (black curve). **d** Vertical distribution of correlation coefficient between shoreline position and total beach volume. HAT, MHWS, MHWN and MSL indicate highest astronomical tide, mean high water spring, mean high water neap and mean sea level, respectively

gap in 2008, 2–4 week sampled topographic surveys were performed at Truc Vert at spring low tide using a centimeter-accuracy Trimble 5700 DGPS. The alongshore coverage increased over the years from about 350–750 m in early 2009 to about 1,500 m in October 2012 onward. The topographic surveys were averaged alongshore to derive a mean beach profile (for more details, see Castelle et al. 2014, 2015 and Splinter et al. 2014a). Figure 1c shows the superimposed mean profiles surveyed from 2005 to 2013 where the elevation is given with respect to the local mean sea level, highlighting the large vertical and cross-shore variability.

The shoreline proxy explaining the largest amount of the total beach volume variability was chosen. The total beach volume was computed by integrating all positive elevations above the local mean sea level up to the backbeach where the topographic elevation remains approximately constant over time, with the total volume at the start of the survey period set to 0. The vertical distribution of the correlation coefficient between the shoreline proxy and the beach volume is reported in Fig. 1d for the 2005–2013 period. The best correlations are obtained for elevations ranging from 1 to 2 m above mean sea level, which approximately corresponds to the mean high water level for neap and spring tides, respectively (Fig. 1c, d). The mean high water level shoreline proxy (1.5 m above the local mean sea level) is used here, which agrees with previous shoreline modeling studies at Truc Vert beach (Castelle et al. 2014; Splinter et al. 2014a).

Figure 2f shows the time series of shoreline position at Truc Vert combining the whole dataset. Error bars indicate the alongshore standard deviation of the 1.5-m iso-contour, which

is a measure of beach three-dimensionality, with a mean error bar length of 7.9 m. The large variability in error bars starting in 2005 reflects the strong beach three-dimensional variability throughout the years. The shoreline positions prior to April 2005 are also included, despite their low accuracy blurring the seasonal variability. Nonetheless, this supplementary dataset further highlights a striking interannual shoreline signal within the entire 2000–2014 period. The seasonal cycles are generally characterized by a succession of accretional and erosional periods centered on the summer and winter, respectively. Spring and fall are both transition periods that can be either accretional or erosional, although a slight mean accretion trend is found for both seasons. The cross-shore amplitude of the interannual variability is 30 to 40 m, which is similar to the amplitude of the seasonal cycle. The whole dataset appears to capture two full cycles of interannual variability (Fig. 2f), with three shoreline minima (erosion) in approximately 2001, 2009 and 2014, and two maxima (accretion) in approximately 2005 and 2012.

Weather regime computation

Assessment of the North Atlantic climate variability is based on two global atmospheric reanalyses produced by the European Centre for Medium-Range Weather Forecasts (ECMWF). The ERA-40 reanalysis (Uppala et al. 2005) is used to compute the weather regime centroids and their daily occurrence for the 1958–2001 period. As the ERA-40 reanalysis does not cover the 2000–2014 study period, the ongoing ERA-Interim reanalysis (Dee et al. 2011), which started in 1979, is used to

compute the daily occurrence of the weather regimes for this study period, assuming the quasi-stationarity of the weather regimes (Michelangeli et al. 1995; Cassou et al. 2004).

Because of a strong seasonal modulation of the North Atlantic atmospheric circulation, and in turn of the wave energy, weather regimes are computed by meteorological season: winter (December, January, and February), spring (March, April and May), summer (June, July and August) and fall (September, October and November). The weather regime centroids are computed as in Sanchez-Gomez et al. (2009), that is, by using the anomaly maps of the 500-hPa geopotential height (Z500) over the North Atlantic Basin

(90°W–30°E, 20–80°N) for the 1958–2001 period. The classification into weather regimes is performed by applying the k -means partition algorithm to the data after reducing the number of degrees of freedom using an EOF decomposition (Michelangeli et al. 1995). Only the first 15 principal components are retained, which explains about 90% of the total variance. For each season the optimal Z500 anomaly field partitioning is carried out with four clusters. Once the centroids are defined, for both reanalyses the weather regime occurrence is computed on a daily basis, such that each day is associated to one of the 16 weather regimes. The similarity criterion is based on the Euclidian distance between the daily Z500 anomaly map and the weather regime centroids. Finally, yearly seasonal occurrence is computed to provide the time series of seasonal weather regime occurrence. For each season of each year, the cumulative occurrence of the four seasonal weather regimes always equals 100% of the time, meaning that the time series are interdependent within each season.

Weather regime impact on wave climate

At Truc Vert and along many other waved-dominated sandy beaches, waves are the primary driver of shoreline change. To support the development of a shoreline evolution model driven by weather regimes, the relation between the weather regimes and the local wave climate is explored on seasonal timescales. This relation is assessed by computing correlation maps between time series of seasonal weather regime occurrence derived from the ERA-40 reanalysis (1958–2001) and seasonal wave parameter anomalies computed over the Bay of Biscay (bordered by the N Spanish and W French coasts, see Fig. 1) using the BoBWA-10kH wave hindcast (Charles et al. 2012b). The wave parameters used are H_s , the mean wave period and the peak wave direction. Because waves are essentially wind-generated, to provide insights into possible relations between weather regimes and waves the seasonal surface wind modification over the North Atlantic Ocean is assessed by computing and analyzing the 10-m seasonal mean wind maps and the 10-m wind mean composites corresponding to the 16 weather regimes.

Statistical weather regime-driven shoreline model

To investigate the predictability of the interannual shoreline variability, a simple model linking seasonal shoreline change and weather regime occurrence is developed. A limited number of weather regimes is used in comparison with existing studies downscaling wave climatology from atmospheric data (e.g., Camus et al. 2014; Laugel et al. 2014). Here, using a small number of well-defined circulation patterns is a necessary requirement both to ease interpretation and to achieve a robust statistical model setup as a higher number of circulation patterns would require a longer shoreline dataset. The model

considers the shoreline position as an auto-regressive process (i.e., it depends linearly on its own previous values) and assumes that, for a given season, the rate of shoreline change is controlled by a linear combination of individual weather regime occurrence. With these assumptions, the simulated shoreline position x_{mod} is calculated on the first day of each season:

$$x_{\text{mod}}(t + \Delta t) = x_{\text{mod}}(t) + u_{\text{mod}}(t) \times \Delta t$$

where t is the time, Δt is the seasonal time step and equals the duration of that season in days (between t and $t + \Delta t$), and u_{mod} is the weather regime-based estimate of shoreline change rate during that season. u_{mod} is obtained from the following season-dependent equation:

$$u_{\text{mod}}(t) = a_{\text{season}} + \sum_{i=1}^3 b_{i,\text{season}} \text{WR}_i(t)$$

where WR_i is the occurrence value of the i th weather regime during a given season, $b_{i,\text{season}}$ is the coefficient associated with WR_i and is season-dependent, and a_{season} is a season-dependent constant. Values of a_{season} and $b_{i,\text{season}}$ are calibrated for each season by performing multiple-linear regression between the seasonal weather regime occurrence and the corresponding time series of measured seasonal shoreline change rate over the period spanning April 2005 to December 2014 (hereafter called the calibration period). For each season only three out of the four time series of seasonal weather regime occurrence are used as these time series are interdependent (see Weather regime computation subsection). Indeed, the sum of the occurrence of the four weather regimes is 100%, such that the occurrence of the fourth regime can be deduced from the occurrence of the three other ones. Using the four time series would therefore add redundant data in the multiple-linear regressions. A preliminary analysis indicates that changing the three weather regimes causes no change to the model output.

Both the measured and simulated shoreline time series are detrended with a linear fit to remove the long-term trend, as this study aims at investigating the interannual variability of shoreline change. The model skill is assessed in terms of the root-mean-square error (RMSE) and coefficient of determination (R^2). Since the topographic surveys were performed at irregular intervals and depending on tide range, there is no measurement concurrent with the model output. To assess model skill, each simulated shoreline position is associated with the average of the measured shoreline positions at ± 15 days of the simulated position. As a last processing step, the measured and simulated shoreline position time series are linearly interpolated and further low-pass filtered with a 2-year cutoff frequency to focus on the interannual shoreline variability.

Results

Weather regimes and wave climate

The four computed winter centroids (Fig. 3a, e, i, m) are very similar in pattern with those described in the literature (Vautard 1990; Cassou et al. 2004) and introduced in the Physical setting section. For the other seasons, the centroids are characterized by similar anomaly patterns, although some significant shifts of the Z500 anomaly position and magnitude are detected, especially during fall (Fig. 3). For clarity, each centroid is denoted by the name of the most similar winter centroid.

The most significant correlation maps are obtained for the winter and summer seasons (Figs. 4 and 5, respectively). For both seasons, the seasonal wave characteristics off the SW French Atlantic coast appear to be strongly related with the weather regimes. High occurrence of winter and summer ZO is associated with an increase in H_s and mean wave period (Figs. 4a, b and 5a, b). During winter and summer, high occurrence of GA is associated with an anticlockwise rotation of the peak wave direction (Figs. 4f and 5f). In addition, high occurrence of winter GA decreases the mean wave period (Fig. 4e) whereas high occurrence of summer GA leads to an increase in H_s (Fig. 5a). High occurrence of winter and summer BL is associated with a slight decrease in H_s (Figs. 4g and 5g). Finally, high occurrence of winter and summer AR drives a clockwise rotation of the peak wave direction (Figs. 4l and 5l) along with a decrease in H_s , which is more pronounced in summer (Figs. 4j and 5j).

Figure 6 reveals that the weather regimes appear to strongly modulate the surface wind patterns over the North Atlantic Basin. While some weather regimes are associated with a strong reinforcement of the mean surface circulation at various locations (e.g., ZO), others lead to a decrease in wind magnitude and drive significant change in the mean surface wind direction (e.g., AR).

The time series of seasonal weather regime occurrence from winter 2000 to fall 2014 and derived from the ERA-Interim reanalysis are shown in Fig. 2a–d. The North Atlantic Ocean atmospheric circulation displays a strong variability on both seasonal and interannual timescales.

Model results

The simulated shoreline position in Fig. 7a indicates that the seasonal cycles over the calibration period are well captured by the model, although the cross-shore excursion is slightly underestimated. Over this period, the RMSE and R^2 calculated between the measured and simulated shoreline positions are 8.6 m and 0.61, respectively. Prior to April 2005, the seasonal cycles are still reproduced, with the low-accuracy data over this period preventing relevant model skill assessment.

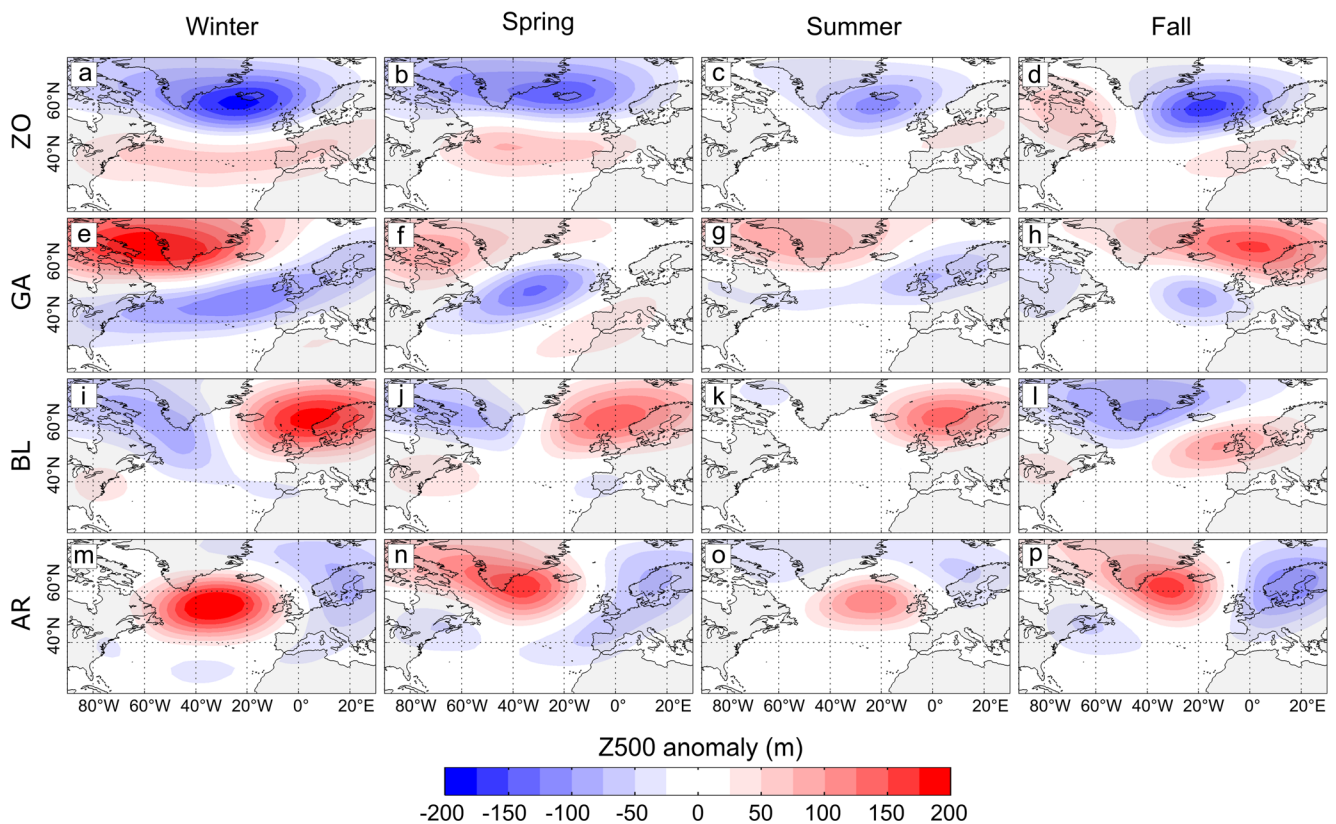

Fig. 3 North Atlantic weather regime centroids for winter (December, January, February), spring (March, April, May), summer (June, July, August) and fall (September, October, November). The centroids are computed from the anomaly maps of the 500-hPa geopotential height

over the North Atlantic Basin obtained from the ERA-40 reanalysis. *ZO*, *GA*, *BL* and *AR* Zonal, Greenland anticyclone, blocking and Atlantic ridge regimes, respectively

Figure 7b shows the interannual signal contained in both time series, highlighting that the model reproduces the interannual variability from April 2005 to December 2014 with excellent skill (RMSE and R^2 of 5.0 m and 0.93, respectively). From 2000 to the end of 2004, the overall slow accretion trend in the measurements is well captured by the model, although there is a substantial shift between the two signals. Therefore, the interannual variability is also well reproduced over the entire period, with a RMSE of 5.9 m and R^2 of 0.70.

Discussion

Weather regimes, wave climate and shoreline change

A detailed inspection of Fig. 6 shows how the weather regimes can affect the wave climate in the Bay of Biscay. The surface wind modifications induced by the weather regimes have a profound impact on wave generation in the North Atlantic Ocean and, in turn, on the waves reaching the Bay of Biscay. Figure 6a–d indicates that during all seasons *ZO* occurrence is characterized by above average surface winds blowing from the W to E, such that *ZO* occurrence should allow energetic swells to develop and propagate toward W

European coasts, which agrees with the results found in Fig. 4a, b and Fig. 5a, b. On the contrary, Fig. 6m–p shows that *AR* occurrence is characterized by a strong reduction or even a disappearance of the W wind component over the central part of North Atlantic Ocean and by an increase in winds blowing from the N–NW over the Bay of Biscay. These combined effects should limit swell occurrence and favor the formation of NW seas in the Bay of Biscay, explaining the wave patterns depicted in Fig. 4j–l and Fig. 5j–l. Figure 6e, g reveals that the maximal zonal surface circulation is shifted southward for winter and summer *GA* occurrence, giving a plausible reason for the anticlockwise rotation of wave direction observed in Fig. 4f and Fig. 5f. The interpretation of the wind composites associated with *BL* occurrence (Fig. 6i–l) is more difficult. However, the slight decrease in H_s observed in winter and summer (Figs. 4g and 5g) could be related to the smaller distance over which westerly surface winds blow in the middle of the North Atlantic Ocean.

To estimate weather-regime impact on shoreline change on seasonal timescales, correlation coefficients (R) between the time series of the seasonal weather regime occurrence and seasonal shoreline change rate are calculated for the 2005–2014 calibration period. A positive value indicates that the

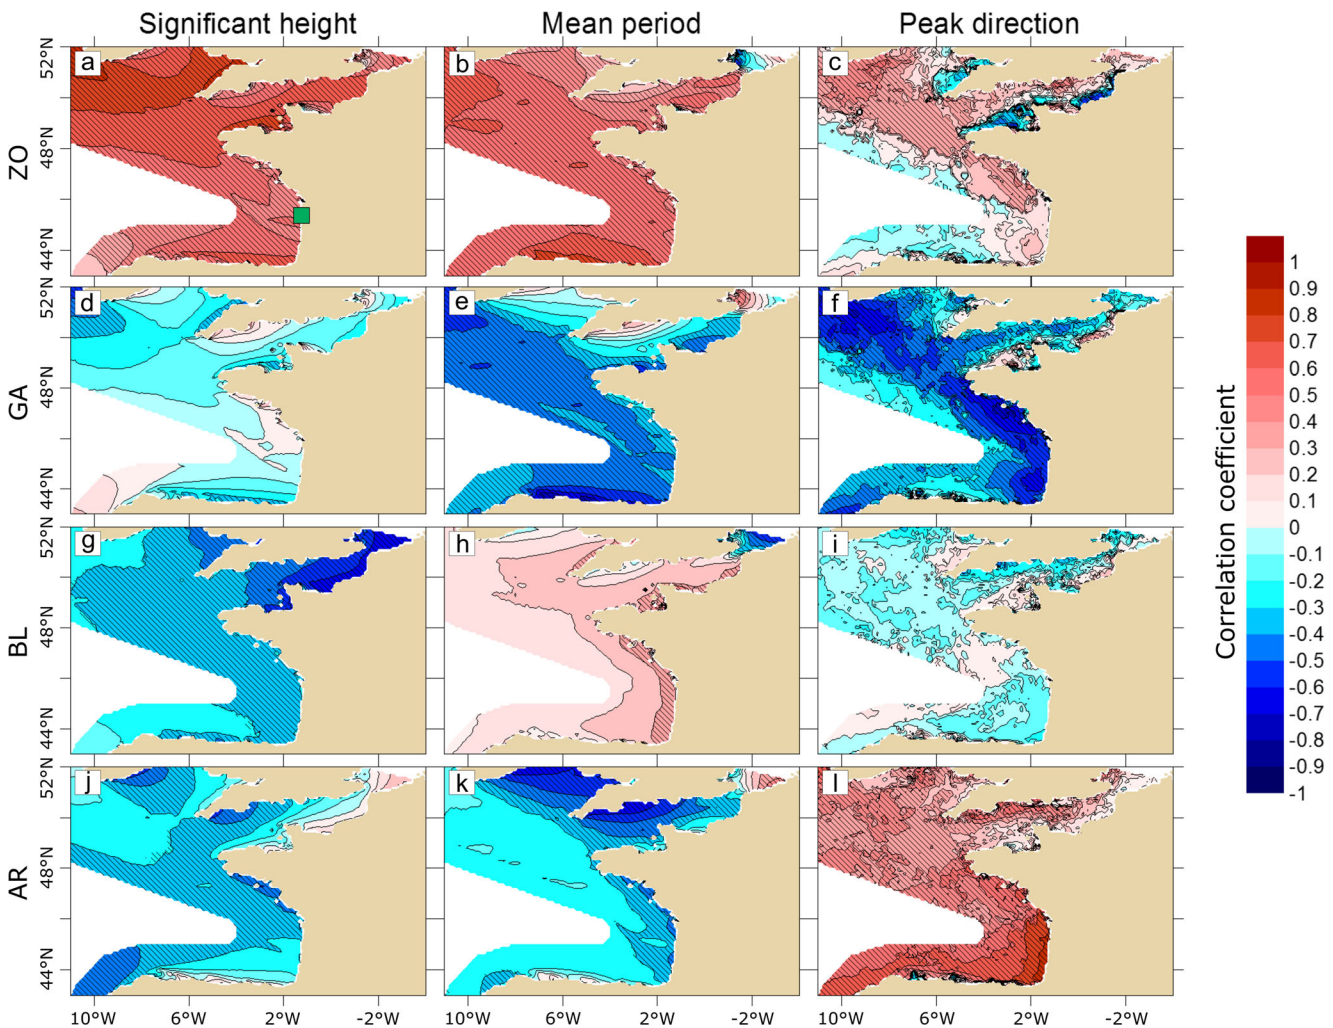

Fig. 4 Correlation maps computed between the winter weather regime occurrence derived from the ERA-40 reanalysis and wave characteristic anomalies calculated from the BoBWA-10kH wave hindcast in the Bay of Biscay for the 1958–2001 period. A positive anomaly in peak direction

corresponding weather regime reduces the seasonal erosion trend or amplifies the seasonal accretion trend. Most of the obtained correlation values are not statistically significant. However, four seasonal weather regimes have significant correlation with p -values ranging from 0.05 to 0.15: in winter, ZO high occurrence increases erosion rate ($R=-0.56$); in spring, AR high occurrence is associated with a decreased accretion rate ($R=-0.60$); in summer, GA and BL high occurrences lead to an increase ($R=0.61$) and a decrease in accretion rate ($R=-0.67$), respectively. It has been proven on many wave-dominated coasts that shoreline change rate is proportional to the incident wave energy, and the energy disequilibrium between this energy and the equilibrium energy for which the coast is stable (Davidson and Turner 2009; Yates et al. 2009). Thus, the statistically significant relationships identified here may be related to weather regime-driven modulation of incoming wave energy. Change in water level induced by weather regime-driven variations of sea-level pressure

(Barrier et al. 2013) and/or onshore winds (Ullmann and Moron 2008; Ullmann and Monbaliu 2010) may also impact shoreline change as storm wave events coinciding with higher water levels result in higher rates of erosion (Ruggiero et al. 2001; Serafin and Ruggiero 2014). However, this was not verified here as it is beyond the scope of this study.

According to the results of the correlation maps (Fig. 4), in winter, only high occurrence of ZO is associated with larger and longer waves offshore of Truc Vert, which is expected to increase beach erosion. During summer, high occurrence of GA is associated with larger waves and an anticlockwise rotation of the peak wave direction (Fig. 5d, f), allowing the wave incidence to be closer to shore normal. Onshore wave-driven sediment transport requires a minimal amount of incident wave energy to move the eroded sand back on the beach. It is hypothesized that, for the summer GA weather regime, slightly above average H_s favors beach recovery at Truc Vert. The results also reveal that, during summer, high occurrence

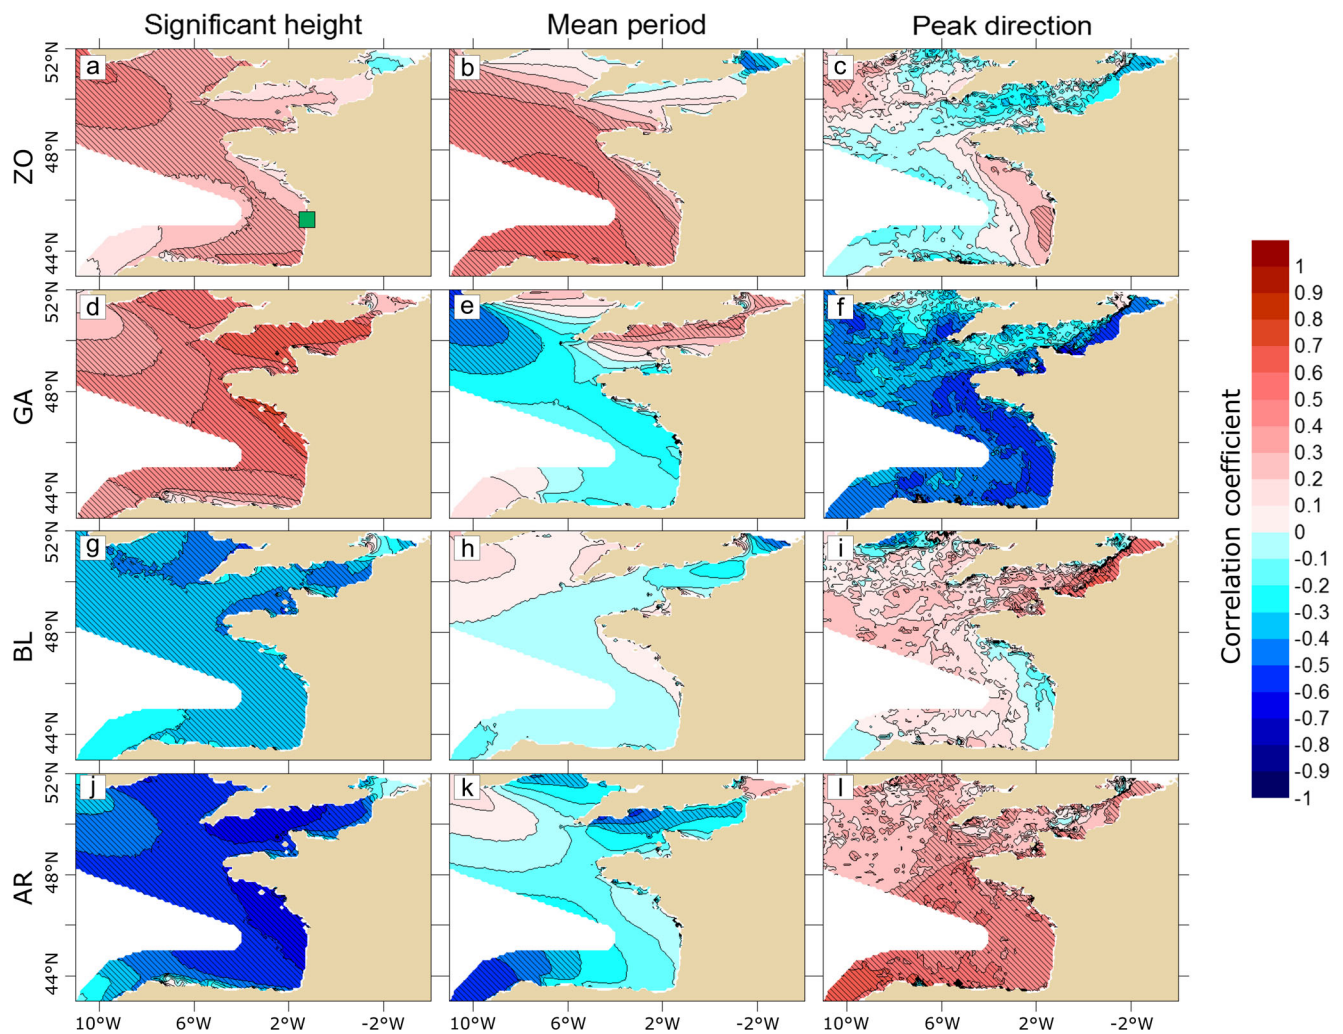

Fig. 5 Same as Fig. 4 for summer

of BL is associated with smaller waves (Fig. 5g) and BL occurrence appears to be anti-correlated to GA occurrence in summer (Fig. 2c). By reducing the occurrence of GA and by causing lower energy conditions, BL high occurrence is expected to slow down beach recovery at Truc Vert. Figure 6n shows that spring AR is characterized by nearly no wind circulation over the central part of the North Atlantic Ocean, and light winds blowing from the N over the Bay of Biscay resulting in very low energy conditions. High occurrence of AR in spring is therefore associated with low incoming wave energy at Truc Vert, which limits post-winter beach recovery.

Shoreline change also strongly depends on antecedent wave conditions (Wright and Short 1984; Davidson et al. 2013; Splinter et al. 2014a) and storm event chronology (Splinter et al. 2014b). Therefore, investigating the individual contribution of the weather regimes to shoreline change on seasonal timescales could be improved by accounting for a “memory” effect. However, the present shoreline dataset spans too short a duration to perform such an analysis.

Weather regime-driven shoreline model

To test the ability of the model to simulate the relationship between the seasonal weather regime occurrence and the interannual shoreline variability, randomization tests are performed. Model input data were replaced by a dataset of 16 random signals following a uniform law with mean and standard deviation similar to the time series of weather regime occurrence. Over 1,000 simulations were performed on random inputs, and the results indicate that the probability to increase model skill is less than 1%. This confirms that the model is not over-calibrated and that there is a physical relation between the combination and succession of the seasonal weather regime occurrence and the interannual shoreline dynamics. According to the above results, large-scale atmospheric fluctuations over the North Atlantic Ocean, described here through the weather regime paradigm, can explain up to 70% of the interannual shoreline variability measured at Truc Vert beach between 2000 and 2014. However, the model

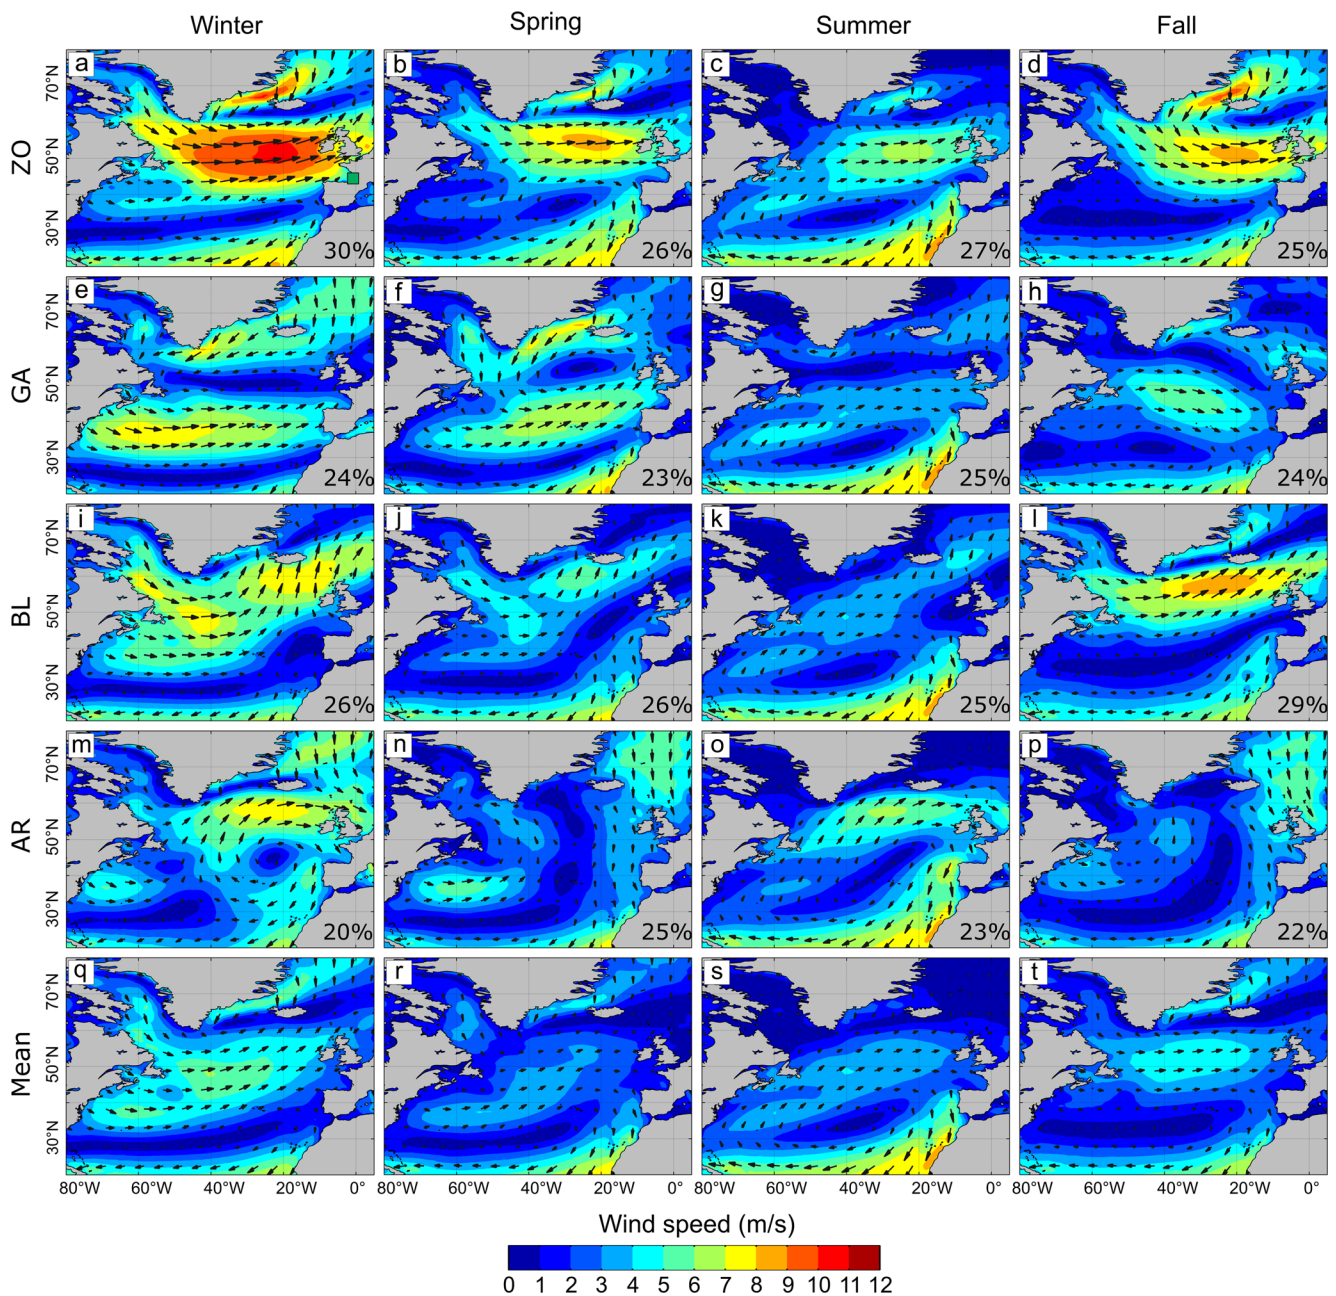

Fig. 6 a–p Mean seasonal wind composites for each weather regime and q–t mean seasonal wind fields derived from ERA-40 10-m wind fields of the 1958–2001 period for winter (December, January, February), spring (March, April, May), summer (June, July, August) and fall (September,

October, November). Percentages Mean seasonal weather regime occurrence. ZO, GA, BL and AR Zonal, Greenland anticyclone, blocking and Atlantic ridge regimes, respectively. Green square (upper left) Truc Vert beach location

underestimates both maxima for erosion and accretion because it solves shoreline change on a seasonal timescale. This is a major limitation compared to equilibrium shoreline models (e.g., Yates et al. 2009) based on time steps of the order of hours. Nonetheless, it is important to note that these models also tend to underestimate maxima for both erosion and accretion (e.g., Splinter et al. 2014a), which can be attributed to the omission of other factors such as tides and sandbar welding to the shore.

To compare the model developed here (hereafter referred to as the RO16 model) with existing wave-driven shoreline evolution models, the model of Yates et al. (2009) is used (hereafter referred to as the YA09 model). The setup of the YA09 model is performed following the method in Castle et al. (2014) using the calibration and simulation periods addressed herein. Results from the YA09 model are superimposed on those from the RO16 model in Fig. 7a. Consistently with the methodology described in the Materials and methods section,

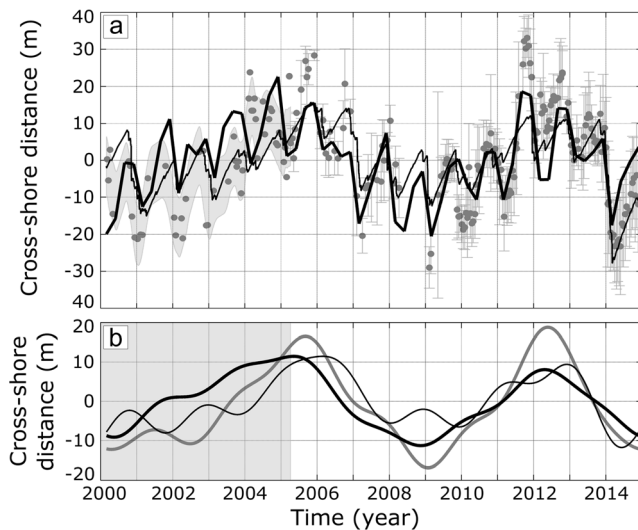

Fig. 7 **a** Measured (gray dots) and simulated (thick black line) shoreline position after detrending. Error bars and gray shading Alongshore variability, as in Fig. 2f. **b** Measured (thick gray line) and simulated (thick black line) shoreline position after detrending and 2-year low-pass filtering. Gray area Period of low-accuracy measurements. Thin black line in **a** and **b** Results obtained with the model of Yates et al. (2009) using the same calibration and simulation periods; model setup based on Castello et al. (2014)

the new simulated shoreline position is detrended, linearly interpolated and low-pass filtered with a 2-year cutoff frequency to extract the interannual variability (Fig. 7b). Over the entire study period the interannual variability is well reproduced by the YA09 model, with a RMSE of 6.0 m and R^2 of 0.69. The YA09 model does not perform better during the calibration period, as the RMSE increases to 6.4 m while the R^2 barely changes (0.70).

The RO16 model is more skillful than the YA09 model during the calibration period presumably because of the large number of input variables and best-fit coefficients that ensure an optimized fitting with field data. Another asset of the RO16 model is that it does not need wave hindcast data, which can require much effort (e.g., model setup, computation, validation) for simulations particularly along rugged coastlines. Equilibrium shoreline models such as the YA09 model were developed to explicitly account for beach memory, which has been known for decades to be critical to short-term beach response to a given storm (Wright and Short 1984). Here, the RO16 model is successful in simulating the interannual shoreline change based on the occurrence of weather regimes without using prior weather regime conditions. This suggests that storm chronology and memory effects are much less important for interannual shoreline change than for short-term beach response.

This new modeling approach should be applicable to other North Atlantic wave-dominated beaches for which the local wave climate is modulated by large-scale atmospheric circulation adequately described by the North Atlantic weather regimes. This would require further calibration, as the best-fit

coefficients are site-specific. For instance, Martínez-Asensio et al. (2016) demonstrated that while NW European Atlantic coasts experience above average wave energy conditions during high winter NAO+, the S European Atlantic coasts undergo the opposite (and vice versa for high winter NAO–). This in turn drives opposite shoreline response, as for instance during the winter 2009/2010. This winter was associated with very high occurrence of the GA regime (Figs. 2a and 3e) with limited erosion at Truc Vert beach (Fig. 2f), while strong erosion was measured at Levante Beach (SW Spain; Rangel-Buitrago and Anfuso 2011). At the other end of the spectrum, beaches with similar wave exposure may exhibit similar links with weather regimes. Comparative data presented in Masselink et al. (2016a, 2016b) reveal that shoreline change patterns on interannual timescales are very similar at Perranporth beach (SW England) and Truc Vert beach. Future work should involve application of this statistical model to other coasts exposed to waves generated over the North Atlantic Ocean.

Conclusions

This paper introduces the development of a new weather regime-driven shoreline model that explains more than 70% of the shoreline interannual variability observed at a high-energy sandy beach in SW France. This implies that interannual shoreline variability on open sandy coasts can be inextricably linked to natural climatic variability over oceanic basins. Findings from this study are limited to a 15-year shoreline time series at a given site, suggesting the need for continued or new long-term shoreline monitoring programs in contrasting hydrodynamics and geological settings to further test and improve a new generation of weather regime-driven shoreline models.

Acknowledgments This work was financially supported by the Carnot-BRGM scholarship (Carnot 2014 - Action 1) and by the Agence Nationale de la Recherche through the CHIPO project (ANR-14-ASTR-0004-01). The ERA-40 and ERA-Interim reanalyses are available on the ECMWF Public Datasets web interface (<http://apps.ecmwf.int/datasets/>). The authors thank the colleagues, including Stephane Bujan and Sophie Ferreira, and PhD students involved with the topographic data collection at Truc Vert over the last 15 years. Two anonymous reviewers as well as the journal editors are gratefully acknowledged for their constructive comments and corrections that greatly improved the manuscript.
